An Integrated Design and Control Optimization Framework for Hybrid Military Vehicle Using Lithium-ion Battery and Supercapacitor as Energy Storage Devices

Abdullah Al-Mamun, Zifan Liu, Denise Rizzo, Simona Onori*, Senior Member, IEEE

Abstract—One of the existing challenges towards the electrification of military vehicles is the selection of the most suitable energy storage device. Moreover, a single energy storage technology might not provide the most benefit out of powertrain electrification. In this paper, a generalized framework for the simultaneous selection of the optimal energy storage device – in the form of standalone or hybrid solution- and online energy management is presented. This study investigates the cooperation of energy-dense Li-ion batteries and power-dense supercapacitors to assist engine operation in a series hybrid electric military truck. Pontryagin’s Minimum Principle (PMP) is adopted as the energy management strategy in a forward-looking vehicle simulator, in which the optimal design and control parameters are found using particle swarm optimization (PSO). Simulation results show that adopting a hybrid energy storage system (HESS) reduces fuel consumption by 13% compared to the case of battery only hybridized powertrain.

Index Terms— Energy management, Li-ion battery, design optimization, Portraying’s Minimum Principle, Supercapacitor.

I. INTRODUCTION

Thanks to its significant fuel saving potential, the powertrain hybridization technology is finding the path into different vehicle classes, from light-duty passenger vehicles to heavy-duty military trucks [1]. In military applications, hybridization of the powertrain can provide increased tactical capability of military vehicles by increasing the available onboard power, along with reducing the battlefield fuel costs [2], [3].

There are various energy storage system (ESS) candidates for the alternative energy sources in hybrid electric vehicles (HEVs). Li-ion battery technology is the most commonly used device for electrified propulsion systems, nowadays, due to its higher power and energy density and declining cost [4]. Additionally, the power to propel the vehicle can be further supplemented by adding other energy storage systems [5].

Supercapacitors have higher power density compared to the Li-ion battery allowing effective regeneration when the battery cannot operate in regenerative mode [5]. The high pulse power capability, fast transient response, and high efficiency during charge and discharge cycles make supercapacitors a viable ESS choice to be used in conjunction with Li-ion batteries in a hybrid energy storage system (HESS) configuration [6], [7]. This will also have positive implications on battery aging as the high power density storage, i.e. the supercapacitor- can handle the demanded power spikes [8], [9].

In the context of this study, besides an internal combustion engine as the primary mover, a HESS pack consisting of Li-ion battery and supercapacitor is considered in the HEV under study. Proper sizing and power management of such a HESS have the potential to reduce lifecycle cost and weight of the storage system while improving the fuel economy.

In [10], a HESS pack with battery and supercapacitor is designed for an electric bus. The battery pack size is determined with the required minimal electric range, and dynamic programming (DP) is used to find the supercapacitor pack size that minimizes the life cycle cost. In [11], for a HESS pack in a fuel cell HEV, the power rating of each energy storage device is scaled up or down to quantitatively assess the significance of appropriate sizing on system volume/mass and battery lifetime. In [12], authors present applications of HESS, such as smart grid and HEV using design optimization techniques, including genetic algorithm (GA), particle swarm optimization (PSO) and simulated annealing (SA). The above studies look only at optimizing the size of the HESS for given rule-based energy management strategies. In contrast, many studies focus on developing control strategies for a given ESS size to achieve certain control objectives, such as minimizing fuel consumption, battery degradation, etc. Those strategies can be categorized into heuristic, near-optimal and optimal ones. Heuristic strategies are usually rule-based [13], [14] and low pass filter-based [15], [16]. Despite their straightforward implementation, a large number of calibration effort is required. Optimal control strategies include DP [17], [18], Pontryagin’s minimum principle (PMP), and Equivalent Consumption Minimization Strategy (ECMS) [19], [20]. They generate optimal control sequence with apriori information of the drive cycle and set the optimal performance benchmark, making themselves suitable for off-line applications. For on-line implementation, near-optimal EMS strategies can be used to pursue the best achievable system efficiency. The model predictive control (MPC) [5], [21], adaptive PMP/ECMS [22], have been discussed for HEV with HESS. They require adaptive tuning of a set of parameters to meet varying real-world power demands. However, to explore the full potential of a HESS configuration in an HEV, the component sizing and energy management should be optimized in an integrated manner.
Combined design optimization and energy management are often solved in a layered approach. In [23], the GA and rule-based EMS were used to simultaneously optimize the monetary cost and the fuel economy of an HEV with a fuel cell, battery, and supercapacitor. The power and SOC limits of the rules and the pack sizes are optimized simultaneously. The authors of [24] minimize the monetary cost and battery degradation for an HEV with engine and battery and supercapacitor. In the outer loop, GA iterates across the design space for optimal sizing parameters while in the inner loop, DP searches for optimal control sequences. The design and control parameters are sought iteratively in a two-layer framework. Convex programming recently arises as an effective approach to tackle the HESS design and control problem bringing less computational burden if compared with DP [25], [26]. However, a large number of model simplifications into convex forms are needed which may neglect important vehicle and component dynamics. The investigation of [27] introduced the coupling of GA and ECMS for multi-objective optimization of an HEV with the engine, battery, and supercapacitor. A multi-criteria decision making (MCDM) technique is used to choose among the solutions with conflicting goals. From this method, it is often difficult to understand the impact of design and control variables on a specific objective which is of principal importance, such as fuel consumption of military vehicles.

The above literature presents the benefits of using HESS configuration which motivates this paper to further explore the combined design optimization and energy management of HESS for military vehicle hybridization. However, a rigorous mathematical formulation and solution approach that is computationally efficient and general enough for a wide range of ESSs and powertrain configurations are still missing in the existing literature. This paper lays the foundation of a new optimization framework that simultaneously accounts for both the control and design variables of a hybrid or electric vehicle powertrain. This paper specifically develops an approach using PMP and Particle Swarm Optimization (PSO) for combined design optimization and energy management of a HESS in an HEV to minimize fuel consumption over a given drive cycle.

The proposed solution method pursued in this work is based on the construction of the Hamiltonian function defined in a way to include both sizing (number of Li-ion cells and number of supercapacitor cells) and control (power split among the engine, the battery pack, and the Supercapacitor (SC) pack) variables. The proposed optimization approach also allows the inclusion of additional optimization objectives which might be important for different vehicle types and classes. In the proposed framework, we allow one of the co-states of the PMP to dynamically vary over time. Therefore, the proposed optimization framework can be extended to plug-in HEV (PHEV) design and energy management where the assumption of a constant co-state does not hold [28]. To the best of our knowledge, this is the first work that formulates such a generalized and combined design and control optimization framework that is applicable across a wide range of vehicle classes and also across a wide range of electrification choices.

The paper is organized as follows. The models of the vehicle, the battery, the supercapacitor and other components are introduced in Section II. The PMP, the PSO, and their integrated formulation are discussed in Section III. Next, five military drive cycles are used under the integrated optimization framework to find the ESS sizing and energy management strategy across different driving conditions and results are presented in Section IV. Conclusions and future work are outlined in Section V.

II. MODEL DESCRIPTION

This study uses a notional series hybrid version of a Mine-resistant Ambush-protected all-Terrain Vehicle (M-ATV) shown in Fig. 1 [29]. A powertrain model of the series hybrid M-ATV, obtained from [30], comprises a genset (Navistar 6.4L 260kW diesel engine + 265kW generator), four 95kW brushless permanent magnet direct current (BLPMDC) in-hub motors, and a Lithium Iron Phosphate (LFP) battery pack. In the battery pack, the number of LFP cells in series ($N_{p,LFP}$) is 130 and the number of cells in parallel ($N_{p,LFP}$) is 10. The genset and the battery pack are connected to the power bus which provides electric power to the four in-hub motors. The vehicle simulator is set up in a Simulink environment where a PID controller is used as a driver model to find the required propulsion power by minimizing the vehicle speed following error. Longitudinal dynamics equations are used in the simulator to simulate the vehicle motion and the genset and the motors are represented by their quasi-static efficiency maps. Details of the vehicle simulator can be found in [30]. The vehicle simulator has a feedforward fuel control logic which is removed to reduce the number of tuning parameters. The performance of the obtained HEV simulator in terms of fuel consumption without the feedforward fuel control is considered as the baseline against which the solution of the proposed optimization algorithm is compared. A low-pass filter based EMS is used in this simulator to split the power between the genset and the battery pack. Since the existing EMS is not optimized, in our previous work [31], we have implemented an optimal control strategy to obtain the benchmark solution in terms of power split and optimal battery size where the Nickel Manganese Cobalt (NMC) battery chemistry is used instead of LFP.

![Fig. 1. A Mine-resistant Ambush-Protected All-Terrain Vehicle (M-ATV) [29].](image-url)

To further explore the benefit of hybridization using more than one energy storage system, in this study, we have considered a HESS configuration including an NMC Li-ion battery pack and a supercapacitor pack. A semi-active
configuration is utilized in the HESS configuration where the supercapacitor pack is connected to the power bus through a DC-DC converter as shown in Fig. 2. The optimal control strategy splits the total power required by the four in-hub motors, \( P_{\text{req}}(t) \) into power demanded from the battery pack \( P_{\text{pack,Li}}(t) \), the SC pack \( P_{\text{pack,SC}}(t) \), and the genset \( P_{\text{gen}}(t) \).

A. Lithium-ion Battery Model

In the HESS configuration, the electrical behavior of the NMC battery pack is modeled by a first-order equivalent circuit model (ECM) whose parameters are temperature dependent. Fig. 3a shows the circuit diagram where \( E_o \) represents the open circuit voltage (OCV) of the cell, which is a function of the cell state of charge (SOC), and \( I_{\text{cell}} \) is the input current (positive in discharge):

![Battery Model Diagram](image)

Fig. 3. (a) First-order equivalent circuit model used to model the dynamic behavior of NMC Li-ion battery. (b) Measured open circuit voltage of the NMC Li-ion cell as a function of the state of charge under a temperature of 23°C and 45°C [31].

The series resistance \( R_o \) captures the internal loss of the cell including the current collector. The RC pair, with a resistance \( R_i \) and capacitance \( C_i \), captures the diffusion dynamics of the cell. The equations of the battery ECM are:

\[
\begin{align*}
\dot{V}_{C_1} &= -\frac{V_{C_1}}{R_i C_i} + \frac{I_{\text{cell}}}{C_i} \\
\dot{\text{SOC}} &= -\frac{I_{\text{cell}}}{Q_{\text{nom}}} \\
V_{\text{cell}} &= E_o - R_o I_{\text{cell}} - V_{C_1}
\end{align*}
\]

where \( Q_{\text{nom}} \) is the nominal capacity of the cell, and Eq. (3) provides the relation for the voltage response of the cell, \( V_{\text{cell}} \) as a function of the model parameters and input, \( I_{\text{cell}} \). The parameters \( (R_o, R_i, C_i) \) in the above model are assumed to be functions of state of charge, temperature and current directionality (charge vs. discharge). Data collected from capacity and hybrid pulse power characterization (HPPC) tests performed at the Battery Aging and Characterization (BACH) Laboratory at Clemson University were used to identified the parameters [31].

A two-state thermal model for Li-ion borrowed from [32] is used in this work to capture the dynamic temperature variation of the NMC Li-ion cell during charge and discharge. Parameters of the thermal model Description of the model equations, model parameter identification, and validation are provided in previous publication by authors [31].

B. Supercapacitor Model

The supercapacitor cell is modeled in this work by a second-order ECM consisting of two capacitor-resistor branches similar to [33], as shown in Fig. 4. The \( R_f C_f \) branch captures the fast dynamics of the order of few seconds and the \( R_d C_d \) branch captures the delayed dynamics of minutes.

![Supercapacitor Model Diagram](image)

Fig. 4. The second-order supercapacitor equivalent circuit model.

The equations comprising the electrical model are as follows:

\[
\begin{align*}
\dot{V}_{C_f} &= \frac{I_f}{C_f} \\
\dot{V}_{C_d} &= \frac{I_d}{C_d} \\
I_{SC} &= I_f + I_d \\
V_{SC} &= I_f R_f + V_{C_f} = I_d R_d + V_{C_d}
\end{align*}
\]

where, \( C_f, C_d \) are the capacitances of the capacitors in the fast and delayed dynamics branches, and \( V_{C_f}, V_{C_d} \) are the corresponding voltages across the capacitors. The resistances of the fast and delayed dynamics branches are \( R_f, R_d \). The currents flowing into the fast and delayed branches are \( I_f, I_d \), respectively, positive current during charge is assumed. The terminal voltage and current through the system terminals are denoted as \( V_{SC} \) and \( I_{SC} \), respectively.

A first-order thermal model is used to capture the supercapacitor temperature change during charge and discharge:
\[ C_{SC} \dot{T}_{SC} = I_{SC}^2 R_f - h_{SC} (T_{SC} - T_{amb}) \]  

where, \( C_{SC} \) is the heat capacity of the cell, \( T_{SC} \) is the core temperature, and \( h_{SC} \) is the effective heat transfer coefficient of a cell. The parameters of a BCAP1500 supercapacitor [34] are identified from a pulse current profile and shown in Fig. 5. The comparison of the model terminal voltage with the measured terminal voltage is also shown in Fig. 5.

The identified electro-thermal model parameters are compiled in Table I.

### C. DC-DC Converter Model

In this work, the SC pack is connected in parallel to the power bus through a bi-directional DC-DC converter in a semi-active configuration shown in Fig. 6. A DC-DC converter takes an unregulated voltage as the input and produces a regulated output voltage by means of pulse-width modulation (PWM) [35]. The DC-DC converter works in two distinct modes: “Buck” and “Boost” mode. In this work, the DC-DC converter is used for voltage conversion between the DC bus and the supercapacitor during charge and discharge of the supercapacitor. The mode of operation of the DC-DC converter changes due to i) change in the direction of supercapacitor power flow, \( P_{SC} \) during charge and discharge, and ii) the difference between the supercapacitor pack voltage, \( V_{SC} \), and the DC bus voltage, \( V_{batt} \). Table II shows the equivalent circuit models of the DC-DC converter in different operating modes. In a real system, the single pole double throw (SPDT) switch shown in the circuits of Table II is realized by semiconductor devices such as MOSFETS, diodes, etc. The inductor \( L \) and the capacitor \( C \) form a low pass filter which allows only the DC component of the input voltage to pass through. The internal loss in the DC-DC converter is modeled by assuming a resistance \( (R_L) \) of the inductor winding \( L \). The voltage conversion is achieved through high frequency switching between position 1 and position 2 and by generating a rectangular wave form. During switching, the fraction of the time the switch is in position 1, determines the output voltage and is defined as the duty cycle. Duty cycle for buck mode \((0 \leq D_{buck} \leq 1)\) and boost mode \((0 \leq D_{boost} \leq 1)\) are different due to their direction of conversion [35].

Fig. 6. Input and output voltage of a switching DC-DC converter.

Table II also shows four different settings under which the DC-DC converter is operated when used in the HESS configuration. During discharge of the supercapacitor, \( P_{SC} > 0 \), the supercapacitor voltage \( V_{SC} \) is the input terminal voltage of the DC-DC converter and the DC bus voltage \( V_{batt} \) is the output terminal voltage. In that case, if supercapacitor voltage is higher than the DC bus voltage \((V_{SC} > V_{batt})\), the converter operates in Buck mode. On the other hand, if the supercapacitor voltage is lower than DC bus voltage \((V_{SC} < V_{batt})\), the converter operates in Boost mode. A similar condition arises when the supercapacitor pack is charged through power coming from the DC bus. In that case, the DC bus voltage \( V_{batt} \) is the input terminal voltage of the DC-DC converter and the supercapacitor voltage \( V_{SC} \) is the output terminal voltage. Similar to discharging, two conditions arise during charging given the relative magnitude of voltage in the input and terminal output of the converter. Power losses during voltage conversion affect the conversion efficiency of the DC-DC converter, which is a function of the internal resistance \( R_L \) of the converter, the duty cycle, and the resistance of the output terminal determine the final converter efficiency. Since the output terminal changes upon the direction of current, the efficiency of the converter depends on the battery pack resistance, \( R_{batt} \), during boost mode and supercapacitor pack resistance, \( R_{SC} \), in the buck mode.

For each mode in Table II, first, the voltage conversion ratio is found by dividing the output terminal voltage by the input terminal voltage [35]. The efficiency is computed as the ratio of power at the output terminal and the input terminal of the DC-DC converter. Expanding the equation of power and using the voltage conversion ratio, the expression of efficiency is obtained as a function of duty cycle, internal resistance, and resistance of the output terminal of the DC-DC converter \( \eta(R_L, D_{boost}, D_{buck}, R_{batt}, R_{SC}) \). The efficiency characteristics
in the Buck and Boost mode are plotted in Fig. 7 as a function of duty cycle and ratio of resistances ($R_l/R$) where $R$ is either $R_{SC}$ or $R_{batt}$ depending on the direction of current. Since the converter efficiency vary significantly with the duty cycle and resistance of the output terminal, it is important to take the efficiency calculation into account when designing a HESS configuration [35]. In this work, a commercial SIEMENS SINAMICS DCP 120 kW DC-DC converter is chosen to be used with the supercapacitor pack. The internal resistance of the converter, which is attributed to the inductor resistance, $R_I$, is assumed to be 0.01 $\Omega$ [36]. The manufacturer limits on voltage, current and power of the DC-DC converter are listed in [37].

### III. PROBLEM FORMULATION AND SOLUTION APPROACH

The goal of this work is to develop a generalized design optimization and energy management framework for a military HEV equipped with a hybrid energy storage system. The traditional approach to such a problem has been to use a layered approach where, typically an exhaustive search algorithm is used in the outer layer to select the design parameters, whereas an energy management algorithm is designed in the inner layer by either borrowing tools from optimal control theory or through some heuristics/rule-based strategy. Such a two-layer iterative process though can lead to unpractical computational time and complexity. This work formulates a combined design optimization and energy management problem and outlines a solution approach which relies on the construction of the Hamiltonian function that integrates both design and control variables. The optimality of the Hamiltonian function can be ensured by enforcing the necessary conditions using PMP.

The goal is to minimize the overall fuel consumption, $J$, over a given drive cycle within the time horizon $[0, t_f]$:

$$J = \int_0^{t_f} \dot{m}_{fuel} (P_{gen}) dt$$

where, $\dot{m}_{fuel}$, is the engine fuel consumption rate (kg/s) and $P_{gen}$ is the power delivered by the engine-generator set (genset). The total electrical power required by the motors is:
The HESS design variable $P_{req}(t) = P_{gen}(t) + P_{HESS}$ can be written as:

$$P_{gen}(t) + P_{pack,Li}(t) + P_{pack,SC}(t)$$

where, $P_{pack,Li}(t)$ and $P_{pack,SC}(t)$ are the battery pack power and SC pack power, respectively.

The total fuel consumption $J$ can be expressed as a function of power delivered from the battery pack $P_{pack,Li}(t)$ and the SC pack $P_{pack,SC}(t)$ to supplement the genset power $P_{gen}(t)$ at each time instant as:

$$J = \int_0^{t_f} \dot{m}_{fuel} \left( P_{pack,Li}(t) + P_{pack,SC}(t) \right) dt$$

Assuming homogeneity in the packs, the battery pack power in Eq. (19) can be expressed as a product of the number of Li-ion cells in series ($N_{p,Li}$), the number of Li-ion cells in parallel ($N_{p,Li}$), and the power delivered by a single Li-ion cell ($P_{cell,Li}(t)$). Similarly, the supercapacitor pack power can be expressed as a product of the number of supercapacitors in series ($N_{p,SC}$), the number of supercapacitors in parallel ($N_{p,SC}$), and the power delivered by a single supercapacitor cell ($P_{cell,SC}(t)$). Using these relations in Eq. (19), one obtains:

$$J = \int_0^{t_f} \dot{m}_{fuel} \left( N_{p,Li} \cdot N_{p,Li} \cdot P_{cell,Li}(t) + N_{p,SC} \cdot N_{p,SC} \cdot P_{cell,SC}(t) \right) dt$$

In this work, it is assumed that the number of Li-ion cells in series is known and found by dividing the DC bus voltage with the nominal voltage of an NMC Li-ion cell. The above cost function is constrained by the system states.

In the supervisory controller module, a simpler model of the Li-ion battery and SC are used to reduce computational complexity. A zero-order model of the Li-ion battery and a first-order model for the SC are used, where the voltage across the capacitor of the delayed dynamics branch is the only state of the SC.

In the following generalized formulation, the battery SOC is indicated as $x_1(t)$ and the voltage across the capacitor of the delayed dynamics branch $V_{cd}$ in the SC model is indicated as $x_2(t)$. The HESS state vector is then defined as $x(t) = [x_1(t) \ x_2(t)]$, where:

$$\dot{x}_1(t) = -\frac{I_{pack,Li}(t)}{Q_{pack}} = -\frac{I_{cell,Li}(t)}{Q_{nom}} = \frac{E_0 - \sqrt{E_0^2 - 4R_0P_{cell,Li}(t)}}{2R_0Q_{nom}}$$

$$\dot{x}_2(t) = -\frac{I_{pack,SC}(t)}{C_{pack}} = -\frac{I_{cell,SC}(t) \cdot N_{p,SC}}{C_d} = \frac{V_{cd} - \sqrt{V_{cd}^2 - 4R_0P_{cell,SC}(t) \cdot N_{p,SC}}}{2R_0C_d}$$

The HESS design variable vector is indicated as $\nu = [N_{p,Li} \ N_{p,SC} \ N_{p,SC}]^T$. The control variables are the instantaneous power form a single Li-ion cell and SC cell, $u(t) = [u_1(t) \ u_2(t)] = [P_{cell,Li}(t) \ P_{cell,SC}(t)]^T$. The admissible set of design and control variables is defined as $\nu = [\nu_{min} \ \nu_{max}]^T$ and $u(t) = [u_{min}(t) \ u_{max}(t)]^T$, respectively. The goal of the optimization problem is to find the admissible design and control variables $\pi \in \Pi = [U(t) \ \nu]$: $\pi(t) = \{u(t) \in U(t) \ \nu \in \nu\}$ such that

$$J = \int_0^{t_f} \dot{m}_{fuel}(\pi(t)) dt$$

is minimized while subject to: (21), (22), and

$$\nu_{min} \leq \nu \leq \nu_{max}$$

$$x(t_f) - x(t_0) = \Delta x = 0$$

$$u_{min}(t) \leq u(t) \leq u_{max}(t)$$

$$x_{min}(t) \leq x(t) \leq x_{max}(t)$$

$$T_{y,min} \leq T_y(t) \leq T_{y,max}$$

$$\omega_{y,min} \leq \omega_y(t) \leq \omega_{y,max}$$

$\gamma = \text{engine, motor, generator}$

Based on the above problem formulation, a solution method is proposed where the Hamiltonian function is constructed in such a way that both design and control variables are included. PMP is a powerful tool that provides a set of necessary conditions of optimality in terms of the Hamiltonian function. The optimality is guaranteed by selecting the optimal control candidate that produces the lowest total cost.

The PMP has been successfully used in the literature to solve the optimal power split problem in HEVs [39]. In this work, given the cost function (17), the Hamiltonian function is defined as follows:

$$H(t, x(t), \lambda(t), u(t), \nu) = \dot{m}_{fuel}(u(t), \nu) + \lambda(t)^T \cdot f(t, x(t), u(t), \nu)$$

where $f$ is the vector of the state dynamics in Eq. (21) and (22) and $\lambda(t)$ is the vector of co-states, e.g., $\lambda(t) = [\lambda_1(t) \ \lambda_2(t)]^T$ carrying the units of kilograms, equivalent to the amount of fuel saved thanks to the utilization of energy storage devices. Furthermore, the co-states variables act as penalty on the energy storage devices usage: a higher value of $\lambda(t)$ discourages the controller to use the available energy in the battery and the SC pack, whereas a low value assigned to the co-states signifies that the usage of the battery/SC is preferred (in the sense that is cheaper) to the use of the ICE. The necessary conditions for optimality are the following:

State dynamics:

$$\dot{x}_1(t) = \frac{\partial H}{\partial \lambda_1} = \frac{E_0 - \sqrt{E_0^2 - 4R_0u_1(t)}}{2R_0Q_{nom}}$$

$$\dot{x}_2(t) = \frac{\partial H}{\partial \lambda_2}$$
\[
\dot{x}_2(t) = \frac{\partial H}{\partial x_2} = \frac{V_{cd} - \sqrt{V_{cd}^2 - 4R_d u_1(t)}}{2R_d C_d}
\]  

(27)

Co-state dynamics:

\[
\dot{\lambda}_1(t) = -\lambda_1 \frac{\partial H}{\partial x_2} = -\lambda_1 \frac{\partial}{\partial x_1} \left( \frac{E_0 - \sqrt{E_0^2 - 4R_0 u_1(t)}}{2R_0 Q_{nom}} \right)
\]  

(28)

\[
\dot{\lambda}_2(t) = -\lambda_2 \frac{\partial H}{\partial x_2} = -\lambda_2 \frac{\partial}{\partial x_2} \left( \frac{V_{cd} - \sqrt{V_{cd}^2 - 4R_d u_2(t)}}{2R_d C_d} \cdot N_{s,sc} \right)
\]  

(29)

Charge sustainability:

\[
x(t_f) - x(t_0) = \Delta x = 0
\]  

(30)

Optimality:

\[
H(t, x^*(t), \lambda^*(t), \pi(t)) \geq H(t, x(t), \lambda(t), \pi(t))
\]  

(31)

The optimal solution \(\pi^*(t)\) is such that

\[
\pi^*(t) = \arg \min_{\pi(t) \in \Pi(t)} H(t, x(t), \lambda(t), \pi(t))
\]  

(32)

In HEV charge sustaining operation, SOC is usually constrained within a narrow window, within which, the open circuit voltage \(E_0\) and the resistance \(R_0\) can be assumed constant thus making \(\dot{x}_1(t)\) depend only on battery power \(u_1(t)\). Therefore, from Eq. (28), \(\lambda_1(t)\) is an unknown constant [5]. However, the same assumption cannot be applied to SC since the equation of co-state is an explicit function of the state \(x_2(t)\).

A. Implementation Methodology

To carry out the simultaneous design and control optimization, a PSO technique is chosen and integrated within a PMP framework to optimize both the design variables (energy storage systems sizing) and the control variables (power-split decision). When minimizing the Hamiltonian function in Eq. (25), the value of co-states must be optimally tuned to achieve charge sustainability, and in the PSO algorithm the constant co-state corresponding to the Li-ion pack (\(\lambda_1\)) and the initial value of the dynamic co-state corresponding to the SC pack (\(\lambda_2(0)\)) are treated as the control variables. To find the optimal set of design and control variables (\(N_{p,li}, N_{s,sc}, N_{p,sc}, \lambda_1^*, \lambda_2^*(0)\)), first the upper and lower limits for all variables are specified. The inbuilt `particleswarm` function in MATLAB is used in this work, where each particle comprises a vector of variables randomly generated within the limits. The particles are evaluated by running the vehicle simulator over a designated drive cycle and the Hamiltonian function is minimized at every time step and the power split among the engine, battery pack and supercapacitor pack is found along with the overall fuel consumption. The particles are then evaluated based on the overall fuel consumption. The process is repeated until a certain number of iterations are completed or until the change of the objective function is very small in subsequent iterations. The flow chart of the overall process is described in Fig. 8. The use of PSO instead of the widely used GA arises from the fact that PSO outperforms the GA in terms of computational efficiency [40]. The bounds are found based on the design constraints of the vehicle and preliminary assessment of the impact of the co-state on charge sustainability. In this work, it is assumed that the battery pack is directly connected to the vehicle power bus and the DC bus voltage is the same as the battery pack voltage. From this assumption, the total number of NMC Li-ion cells in series are found to be 116 and used as a known design parameter 1. The optimization algorithm is then designed to search for a HESS configuration where the energy capacity of the battery pack can vary over a wide range, roughly from 12% to 110% of the energy capacity of the original battery pack of the baseline vehicle. Given the number of cells in series as 116, 12% and 110% of the energy capacity of the baseline corresponds to a parallel string length ranging from 1 to 13 cells, respectively. On the other hand, the bounds on supercapacitor pack size are selected from the ability of the DC-DC converter to convert voltage with a high conversion efficiency. From Fig. 7, one can see that the conversion efficiency is lower in the Boost mode than the Buck mode. Therefore, considering only the Boost mode efficiency for finding a suitable range of supercapacitor pack size is sufficient to ensure the desired efficiency in the Buck mode. In this work, it is assumed that the efficiency of the DC-DC converter should not fall below 80%. From this assumption, the minimum and maximum number of supercapacitor cells are obtained as:

\[
V_{min, DC/DC} \leq N_{s,sc} \cdot \eta_{DC-DC, min} \cdot V_{SC, nominal} \leq V_{DC \ bus}
\]  

(33)

where, \(V_{min, DC/DC}\) is the minimum voltage of the supercapacitor pack that the DC-DC converter can convert, \(\eta_{DC-DC, min}\) is the minimum required efficiency of the DC-DC converter, \(V_{SC, nominal}\) is the nominal voltage of the supercapacitor, and \(V_{DC \ bus}\) is the DC power bus voltage. The minimum required efficiency of the DC-DC converter is selected to be 80% in this work. From the above inequality, the relation for the bound on the number of SC cells in series is found as follows:

\[
\frac{V_{min, DC/DC}}{\eta_{DC-DC, min} V_{SC, nominal}} \leq N_{s,sc} \leq \frac{V_{ess}}{\eta_{DC-DC, min} V_{SC, nominal}}
\]  

(34)

which gives the following numerical bounds:

\[
42 \leq N_{s,sc} \leq 199
\]  

(35)

In the optimization algorithm, the supercapacitor cells in parallel are allowed to vary between 1 and 15 based on the maximum discharge current limit of the DC-DC converter.

---

1 The number of cells in a series string is found by dividing the DC bus voltage (429V) by the nominal cell voltage of an NMC Li-ion cell.
In order to account for the vehicle weight augmentation from the various energy storage system configurations the algorithm updates the weight at each iteration/combination. In the baseline vehicle simulator, a lumped weight for the 26650 LFP Li-ion cells, housing, power electronics, cooling systems, is used. Since the weight of a 18650 NMC cell and supercapacitor cell vary significantly compared to an LFP cell, the weight of the individual NMC and supercapacitor cells is first obtained from manufacturers’ datasheet, and then 40% \(^2\) increase in weight is added to account for the housing and other components of the pack [34].

The optimal power management strategy designed in this work utilizes the energy storage systems under certain operating conditions. For example, in propulsion mode, the battery can only be discharged, wherein in braking mode, both charge and discharge are allowed. In propulsion mode, the supercapacitors can be charged or discharged and they can get charged from the engine only. As a result, all the battery power goes to meet the vehicle power requirements. This condition ensures that the supercapacitor has enough charge to supply any instantaneous power requirement when necessary. To ensure drivability and smooth engine operation, the allowable rate of change of engine power demand is limited to 80kW/sec. During braking, the kinetic energy first goes to charge the supercapacitor and after that to the battery pack. This is a reasonable condition since the supercapacitor can be charged and discharged at a much faster rate than the battery pack.

**IV. SIMULATION RESULTS**

In this section, the optimization problem to find the optimal size of HESS and the corresponding energy management is solved for the notional heavy-duty M-ATV military truck. The results are compared with the baseline vehicle simulator in terms of fuel consumption [30]. Additionally, a battery-only ESS configuration with NMC battery pack, studied in [31] is used for comparative analysis with both the HESS and baseline configurations. The optimization framework is implemented under five military drive cycles. The DCE4 Convoy Escort, DCE5 Urban Assault, Churchville, Munson, Harford drive cycles [41] shown in Fig. 9. The DCE5 cycle mainly describes a low-speed driving scenario with frequent acceleration and braking; the DCE4 cycle instead involves high-speed driving activities. Churchville and Harford cycles often require sharp acceleration and braking, whereas the Munson cycle describes a medium constant speed cruising activity. Churchville and Munson drive cycles are courses at the Aberdeen Proving Ground in Aberdeen, Maryland, while the other three are synthetic cycles.

**A. Lithium-ion Battery-only Configuration**

Before implementing the HESS configuration, it is important to assess and quantify the benefits of vehicle hybridization brought by an optimized battery-only ESS configuration developed in [31]. In this work, the combined design and control optimization algorithm is run over a concatenated cycle made of the five military cycles (shown in Fig. 9) with the decision variables being the number of cells in series \(N_s\), the number of cells in parallel \(N_p\), and the battery co-state \(\lambda\).

The battery pack design and fuel consumption for the baseline and the optimized battery-only configuration are listed in Table III. The table shows that the optimized design and control policy can reduce the fuel consumption by 7.3% compared to the baseline HEV [30], which uses an LFP battery pack of 9.8 kWh. The optimized NMC battery pack has, instead, an optimal energy capacity of 10kWh. A properly designed energy storage system with an optimal power split strategy can reduce the fuel consumption without significantly increasing the energy capacity of the storage system. Figure 10 shows the input velocity, required electrical power by the motors, electrical power from the genset, battery power, and battery \(SOC\). Charge sustainability conditions are met and the fluctuations in power demand are handled mostly by the battery pack unless the battery power limit is reached. The zoomed plot in Fig. 10 shows that the genset provides a steady power

\(^2\) The weight of the selected NMC Li-ion cell and the SC cell are 46 gm and 280 gm, respectively.
whenever possible since frequent shifting in operating points causes the engine to consume more fuel.

Fig. 9. The five military drive cycles used to evaluate the performance of the design optimization and energy management solution proposed in this paper.

In the right zoomed plot in Fig. 10, during a very high acceleration and deceleration, the battery pack reaches its maximum power limit. In this case, the genset provides the rest of the power to maintain the desired vehicle velocity. This behavior confirms that the optimal controller tries to maintain a steady engine operation to reduce fuel consumption as much as possible by using the battery power capacity to its allowable limit. The use of a HESS is motivated in that an additional energy storage with high power capacity can handle the large power demand that might occur during driving.

B. HESS Configuration with NMC Li-ion Battery and Supercapacitor

The design optimization framework using the HESS has five decision variables, three relating to the sizing of HESS itself and the other two relating to the PMP’s co-states. The number of battery cells in series is fixed and determined by dividing the power bus voltage (429 V) by the nominal cell voltage (3.7 V) of an NMC cell. The concatenated drive cycle is used to find the optimal size and power split decision for the HESS configuration. The optimal pack size, energy capacity, and fuel consumption are given in Table III. In the table, the fuel consumption results are also compared among the optimized HESS configuration, optimized NMC Battery only configuration, and baseline LFP battery only configuration. The optimal HESS configuration reduces the fuel consumption for the concatenated cycle by 13.6% compared to the baseline. It is found that the energy capacity needed in the NMC battery pack is only 0.86 kWh, almost one fourth smaller than the SC pack size. This indicates that the impact and role of the battery within the HESS is negligible. The SOC and C-rate profiles of the battery pack shown in Fig. 11 indicate that the battery pack is barely used, and the portion of the drive cycle requiring more participation from the battery is related to frequent start and stop instances and when high power is demanded by the vehicle during high acceleration.

Fig. 12 shows that the supercapacitor voltage fluctuates significantly due to frequent charge and discharge events and the supercapacitor can take on high C-rate requests allowing the engine to be used as less as possible. The power loss in the DC-DC converter is also small during vehicle operation since the efficiency is maintained above 95% all the time. The C-rate and power from the supercapacitor are limited by the power limit imposed by the DC-DC converter.

Fig. 11. Desired vehicle velocity, battery SOC, and C-rate for M-ATV with optimal HESS pack when simulating the concatenated drive cycle consisting of five military drive cycles.

In Fig. 13, the drive cycle is partitioned in regions that highlight the instances when vehicle uses battery pack only, the supercapacitor only, and the battery/SC together. Fig. 13 shows that there is no instance when only the battery pack is used. In 91.1% of the time the SC pack is used and the remaining 8.9% of the time, both the SC and the battery pack are used. The battery pack is only used during the high acceleration and deceleration event to supplement the supercapacitor. Fig. 14 shows the magnitude of the power from the genset, the battery pack, and the SC pack. The engine, the battery pack, and the SC pack power sums up to give the power requested by the in-hub motors to propel the vehicle. The charge and discharge power limits of the supercapacitor pack are limited by the DC-DC converter saturation limits and the engine power is limited by the power limit of the Genset. The PMP finds the optimal split of engine power, battery power and supercapacitor power allowing the engine to operate close to the brake-specific fuel consumption (BSFC) sweet spot. For the concatenated drive cycle used in this study, a small NMC battery pack is selected by the optimization algorithm. However, the use of the small battery pack is also optimized to supplement the engine without violating the charge sustainability constraint. During high acceleration, some portion of the engine power is used to charge the supercapacitor pack. Figure 15 shows that in both cases, i.e. optimized HESS and optimized battery-only configurations, the optimization algorithm ensures that the engine operation is forced on the optimal operating line. Moreover, when HESS is used, a lower average BSFC is obtained, thus confirming the initial results.
The cost, weight, and volume of the HESS pack are additional factors to be considered for vehicle electrification. They can either be considered as additional optimization objectives or added as constraints based on the type, size, and functionality of the vehicle. Military vehicles have a higher degree of flexibility in design compared to commercial vehicles and therefore these factors are excluded from the current study. The proposed optimization algorithm is general enough to incorporate those factors and is currently intended to be considered in future studies.

Remark: In this work, the current and voltage limits of a commercially available DC-DC converter were used. It is known that the physical limits of the converter impose a limit on the power delivered by the supercapacitor pack. A proper selection of the DC-DC converter through optimization or a customized DC-DC converter based on the vehicle power requirement could allow the supercapacitor to better utilize its available power capability.

V. CONCLUSIONS

This paper develops a novel mathematical framework for combined design optimization and optimal energy management of a series hybrid electric vehicle with a HESS. The key element of the proposed framework is in the formulation of the Hamiltonian function, from the PMP strategy, to account for both time varying control variables and design variables. The optimization framework is implemented to minimize fuel consumption of a notional military hybrid electric vehicle by finding the optimal sizes the Li-ion and SC pack and optimal power split among the genset, battery pack and the SC pack. The key findings of this paper are summarized below:

- The simulation results show that for a concatenated drive cycle combining five military drive cycles, the optimal design and energy management algorithm can reduce the fuel consumption by nearly 7.3% for the battery-only case compared to the baseline.
- When using the HESS configuration fuel consumption is reduced by up to 13% compared to the baseline.
- The optimal pack size of the HESS configuration shows that the contribution of Li-ion battery pack is not significant if there is a properly sized supercapacitor available in the HESS configuration. Therefore, there is a high potential for using supercapacitors for military vehicle hybridization even as a standalone storage system.

The future work aims at extending the proposed optimization algorithm to tackle multiple objectives such as battery health degradation, the lifecycle cost of the energy storage system. Active temperature control of the battery pack to prevent thermal runaway and temperature related aging effects is also a part of the future work as well as the extension of the proposed framework to plug-in hybrid electric vehicles (PHEVs) and electric vehicles (EVs).
